My mother who taught me the alphabets ...
My father who taught me how to live life ...

ACKNOWLEDGMENTS

First of all, I thank Allah for giving me all what I have in life. My life is full of his grace and blessings.

Second, I would like to take the chance to thank my parents who always encouraged me to thrive for knowledge and seek the best and my wife who supported me all the way through my Master's degree.

Many thanks to my uncle Professor Amro Al-Qutub for his support and guidance.

Special thanks to my advisor Dr. Rached Ben-Mansour for teaching me three graduate courses, accepting to be my advisor, for his efforts and patience.

I also thank Prof. Esmail Mokheimer and Prof. Mohammed Antar for accepting to be in the committee of my defense. I extend my thanks to all the great faculty members who taught me at KFUPM.

Finally I really thank my friends Hamad Al-Mahmoud, Azzam Al-Farraj, Ahmad Abo-Elyaman and Ghazi Zul-Hazmi for their help at different stages in my way to my Master's degree.

THESIS ABSTRACT

NAME: Majid Tareq Linjawi

TITLE OF STUDY: Modeling Fluid Flow and Heat Transfer in a Porous Ceramic Used for High Concentration Solar Receivers

MAJOR FIELD: Mechanical Engineering

DATE OF DEGREE: May, 2018

This thesis investigates the fluid flow and the heat transfer in ceramic foams, used for high concentration solar receivers; numerically utilizing a simplified geometrical model. The simplified geometry is a truncated octahedron strut consisting of cylindrical beams; ligaments. Three configuration of the geometry are constructed; a basic geometry consisting of a single cell model, two multiple unit cells geometries of 2 by 2 by 2 cells and a 2 by 2 by 3 cells. This novel approach has not been previously used in the literature to study ceramic foams as concentrated solar absorbers. The fluid flow and heat transfer equations within the simplified models are solved numerically using a commercial CFD program. A basic case with an irradiation of $G = 2 \text{ MW/m}^2$ and an air mass flux of $m'' = 12.5 \text{ kg/m}^2 \cdot \text{s}$

is conducted for the three geometric configurations. The radiation, temperature and velocity profiles are reported. The cell efficiency is found to be $\eta = 93.1\%$ at air exit temperature of $T_{g,out} = 447\text{ K}$ for $2^2 \times 3$ multiple unit cells case. Further, a parametric study consisting of more than 500 design points is conducted. A pressure drop and volumetric heat transfer coefficient relations are derived against superficial air velocity. The relations are found to be consistent with published references. The ratio of the solar flux to the mass flux is identified as a key parameter that affect most critical performance parameters of a unit cell. The parametric study showed that the surface absorbtivity of the foam material have a much larger effect on the foam performance than its thermal conductivity. The unit cell simplified method proved to be a simple, robust and accurate method in modeling fluid flow and heat transfer in ceramic foams.

ملخص الرسالة

الاسم الكامل: ماجد بن طارق بن عبدالله لنجاوي

عنوان الرسالة: محاكاة حركة الموائع وانتقال الحرارة في السيراميكيات الإسفنجية المستخدمة كمستقبلات لأشعة الشمس عالية التركيز

التخصص: هندسة ميكانيكية

تاريخ الدرجة العلمية: رمضان 1439 هـ , الموافق مايو 2018

تبحث هذه الرسالة حركة الموائع وانتقال الحرارة في السيراميكيات الإسفنجية المستخدمة كمستقبلات لأشعة الشمس عالية التركيز باستخدام برامج المحاكاة الإلكترونية وافترض شكل مبسط للإسفننج. تم اختيار الشكل المبسط بناء على أبحاث سابقة أثبتت تشابه النتائج المحصلة منه مع النتائج المحصلة من الاختبارات المعملية. قمنا بعرض عملية محاكاة واحدة بالتفصيل وذلك تحت الظروف الآتية : شدة الإشعاع الشمسي: ألفي شمس, معدل تدفق الهواء: 12.5 كيلوجرام في المتر المربع خلال الثانية, معامل التوصيل الحراري: 100 واط في المتر لكل درجة حرارة و معامل امتصاص الأشعة ب 0.9 وحصلنا على كفاءة تعادل 93.1 % ودرجة حرارة للهواء الخارج تعادل 447 كيلفن. ثم تم عمل دراسة موسعة لمعرفة تأثير العوامل المختلفة على الأداء. استخلصت العلاقة بين سرعة حركة الهواء في الإسفننج وبين معامل الاحتكاك ومعامل انتقال الحرارة ووجدت العلاقة مقاربة لما تم استخلاصه من دراسات سابقة. حددت النسبة بين شدة الإشعاع و معدل تدفق الهواء كأهم نسبة تتحكم في أداء المستقبلات الشمسية. ووجد أن لمعامل امتصاص الأشعة أثر كبير على النتائج بينما ليس لمعامل التوصيل الحراري للمكون الصلب للإسفننج أثر ملاحظ. الخلاصة: تم إثبات أن الطريقة المستخدمة في هذا البحث بسيطة وغير مكلفة وتؤدي نتائج دقيقة إلى حد بعيد.

CHAPTER 1

INTRODUCTION

This chapter presents the background of the problem studied in the thesis, explains the motivation for the research and shows its possible range of influence.

1.1 Background

In a world of increasing awareness of the dangers of global warming and fossil fuels emissions; many innovative clean energy generation methods are developed. Solar energy is one of the most promising technologies being proposed. Although solar photovoltaic PV leads the worldwide market in terms of total installed capacity by 50 GW installed in 2015, concentrated solar power is showing a promising future in developing countries with more than 500 MW capacity installed in the last two years [7].

In many concentrated solar receivers, ceramics foams are used as absorbers. A typical arrangement of a parabolic dish with a concentrated solar receiver utilizing ceramic foam absorber is shown in Fig.1.1. In such absorbers, solar radiation

Figure 1.1: Schematic diagram of a solar solar dish [1].

penetrates through the ceramic foam while its intensity decays slowly due to the absorption and scattering of the solar radiation by the solid ligaments of the foam. The absorbed fraction of the radiation causes an increase in the temperature of the material, therefore a stream of fluid - usually air - is forced through the ceramic foam to carry away the absorbed energy. The fluid, which has been heated by the ceramic foam, can be then used in a power generation cycle, or steam reforming process.

1.2 Motivation

However, deep understanding of the behavior of fluid flow and heat transfer within a ceramic foams used as absorbers in concentrated solar receiver has not been achieved. Adequate understanding of the problem is required in order to increase the efficiency and lifetime, and reduce costs and losses for such systems. The lack of concrete knowledge in the area is apparent. For example, there are no

complete published design, operation or optimization guidelines for such systems. These problems were faced during the design of a 20 kW solar dish to be built for research purposes at King Fahd University of Petroleum and Minerals and was the main motivator for this research.

CHAPTER 2

LITERATURE REVIEW

This chapter presents and compares the methods used in the literature to develop a better understanding of the fluid flow and heat transfer phenomena in ceramic foams used in concentrated solar receivers. The chapter concludes with identifying the main knowledge gaps in literature.

There are many methods that can be used to develop a better understanding of the heat transfer and fluid flow and heat transfer phenomena in ceramic foams used in concentrated solar receivers. Experimental methods, detailed modeling, and simplified modeling are the three main methods used in the literature. Each method has its own advantages and drawbacks. For example; at least four separate experimental setups are needed to determine the thermo-physical properties of fluid flow and heat transfer in ceramic foams using experimental methods. Additionally, it is very difficult to simulate the concentrated sun irradiation inside a lab, which is required to obtain the properties of ceramic foams under high irradiation and temperatures. In many cases, researches had to construct actual solar

concentrators and receivers to obtain the fluid flow and heat transfer characteristics of such foams. Therefore, experimental methods are considered expensive and time consuming methods. Detailed modeling can be used to produce accurate simulations and results given the proper inputs are provided correctly. However, this method requires supercomputers and expensive equipment to achieve. Simplified models on the other hand can be used without the expensive computers and equipment but the simplified models results need to be validated and their accuracy has to be tested.

The following sections presents the three main methods used in the literature to study the behavior of fluid flow and heat transfer through ceramic foams.

2.1 Experimental Methods

2.1.1 Pressure Drop

(1) Compressor, (2) by-pass valve, (3) throttle, (4) volumetric meter, (5) pressure drop meter (6) specimen

Figure 2.1: Experimental setup for measuring pressure drop [2]

Using an experimental setup is the easiest way to determine pressure drop for

a flow through porous media including ceramic foams. Various researchers have reported their setup and results [2, 8]. Mostly the results are in form of modified Darcy-Forchheimer equation:

$$-\nabla P = \frac{\eta}{K_1}u + \frac{\rho}{K_2}|u|u \quad (2.1)$$

Where K_1 & K_2 are experimentally determined constants called the specific permeability and the form drag respectively. K_2 can be defined as $1/\beta$ where β is the inertial coefficient. This form of equation is also recommended by the manufacturer of the ceramic foam samples to be used in the proposed solar absorber. A detailed procedure on how to obtain K_1 & K_2 factors is provided in Fluent manual [9].

Since the experimental setup to measure pressure drop across the foams is very simple and give accurate results, other methods were rarely used in determining pressure drop across ceramic foams.

2.1.2 Volumetric Heat Transfer Coefficient

In 1993 Younis and Viskanta used a transient method by inserting a cold sponge sample into a hot gas stream and recording the temperature of the gas outlet during the sponge heating-up process they determined the volumetric heat transfer coefficient h_v [3]. The foam specimens used were made of Al_2O_3 with porosity of 92 % with different pore diameters. The authors correlated the experimental

values using a Nusselt approach with two fitting parameters given by:

$$Nu = C.Re^m \quad (2.2)$$

A schematic representation of their experimental setup is shown in Fig.2.2.

Figure 2.2: Schematic diagram of test apparatus used by Younis and Viskanta to measure volumetric heat transfer coefficient [3]

Recently, Dietrich reviewed the work done in determination of the heat transfer coefficients for solid ceramics and further examined three different porous ceramics made of Al_2O_3 , $OB\text{SiC}$, and $Mullite$ [10]. His final conclusion was a proposed general correlation in form of:

$$Nu = 0.57 * C_{Re} * C_{Geo} * Re^{\frac{2}{3}} Pr^{\frac{1}{3}} \quad (2.3)$$

90% of his data fits in the $\pm 40\%$ of the proposed correlation with OB SiC best fitting the correlation.

In most of the studies reviewed, maximum temperature difference between the porous media and the cooling air was $100^{\circ}C$ and air was the heating the porous media. However for more appropriate results the porous media should be used to heat the passing air, which is similar to the case of solar absorbers. This approach was applied on metal foam by Brendelberger [11]. Experimental results has not been validated under operation conditions of an actual solar receiver where porous ceramic temperature rise up to $1500^{\circ}C$.

Clearly in the literature there is a gap in the adequate validated measurements of volumetric heat transfer coefficient for ceramics foams used as volumetric solar receivers.

2.1.3 Thermal Diffusivity

Due to the nature of porous media which acts like semi-transparent material, thermal diffusivity happens by conduction and radiation. However, at relatively low temperatures, conduction is the dominant contributor to the thermal conductivity [12]. Therefore, many experimental references which study thermal diffusivity using traditional methods of measuring thermal conductivity neglects the effect of radiation, therefore their results are accurate only within the range below $200^{\circ}C$ [12]. However, the temperature of the ceramic foam reaches temperatures up to $1500^{\circ}C$ when used as solar absorbers. Hence thermal diffusivity measurements neglecting the radiation are not adequate. Therefore only experimental studies on evaluation of thermal diffusivity at high temperatures will be considered in this

review.

In 2009 R. Coquard and colleagues proposed an effective thermal conductivity identification method using thermograms obtained from laser-FLASH measurements [13]. Their method permits to evaluate, at ambient and high temperatures, the effective thermal conductivity and two global radiative properties of various metal or ceramic foams, describing the thermal behavior of their equivalent homogeneous semi-transparent materials. Their method is promising since conduction and radiation contributions to heat transfer can be evaluated from a unique experiment [13]. However, their model requires a prior knowledge of the thermal conductivity, extinction coefficient, and scattering albedo. Their results were only validated up to 700 K , which is lower than the required range in volumetric solar absorbers.

In the institute of thermal process engineering at Karlsruhe, two experimental setups were built to measure both axial and radial two-phase (solid and air) thermal conductivity for ceramic sponges. By heating a foam from one direction and blowing cooling air through the sponge, measuring the temperatures at different locations, and applying the steady state energy balance, effective two phase thermal conductivity could be obtained. However, their model neglects radiation and is only limited to temperatures below 200°C . [14, 15]

2.1.4 Radiation Properties

There are three main properties that determines a porous material radiation behavior; absorption coefficient, scattering coefficient, and scattering phase function [16]. Each of the three properties can be spectral, directional and temperature dependent or independent. However, these properties cannot be directly measured using a singlw setup, rather it should be derived from other measurable quantities such as transmissivity, and reflectivity [4]. The derivation of the defining properties from measurable quantities is done by inverse radiative analysis method.

A relatively complex setup made of a radiation source and group of mirrors and reflectors combined with detectors and sensors are required to accurately determine the spectral directional transmissivity and reflectivity. Figure 2.3 shows the experimental setup used by Hendricks to measure radiative properties at infrared region of Oxide bonded Silicone Carbide and Zirconium oxide foams [4].

The obtained results in form of transmissivity, and reflectivity were then analyzed and studied. Using a systematic trial and error approach, a well matching values of absorption coefficient,scattering coefficient, and scattering phase function was obtained. The detailed mathematical derivation of the inverse radiative problem is shown his work [4].

Similar approach was also used by other researchers for different materials such as alumina foams [17] and metal foams [18].

Figure 2.3: Schematic diagram of test apparatus to measure Transmissivity and reflectivity [4]

2.2 Unit Cell Approach

The unit cell approach is based on a simple assumption that a foam can be modeled as repetitive group of idealized unit cells of a certain shape. Hence, studying the local properties of that shape enables us to determine the global properties of the foam. Unit cell approach was utilized to all types of foam properties like pressure drop, volumetric heat transfer coefficient, thermal conductivity, and radiation properties. However, upto the knowledge of the author, it was never utilized to study all the properties at once.

One of the most important aspects in the unit cell approach is the selection of its shape. Therefore, this section starts by summarizing unit cell shapes used in the literature then presents the work done utilizing them.

2.2.1 Unit Cell Shapes

There are two extinct types of unit cells based on the way they are numerically constructed:

- **Volumetric based:** Where the unit cell volume is made of a solid material, then hollowed by certain volumes and shapes.
- **Struts based:** Where the edges of the unit cell are made of ligaments of a certain cross-section and thickness, and the rest of the unit cell volume is hollow.

Figure 2.4: Unit Cell Models Constructed by Volumetric Method.

In volumetric construction; the base shape considered is usually a solid cube which is then hollowed by a hollowing element, usually a sphere or set of spheres. Hollowing spheres number, position, and diameter all effect the final shape and some properties of the unit cell. To match the porosity of modeled foam the diameter of the hollowing spheres should be changed. To match the pore density in Pores Per Inch (PPI) of the modeled foam both the base cube and the hollowing

(a) Tetrakaidecahedron unit cell with cylindrical ligaments and round fillets [2].

(b) Cube simplified unit cell [21].

Figure 2.5: Unit Cell Models Constructed by Nodes and Ligaments Method.

spheres sizes should change. Attention has to be taken when selecting the following spheres positions and diameters to assure that the unit cell has open cell construction and to eliminate any discontinuity in the solid phase. This method easy to construct, however, it has some drawbacks. One drawback is that the produced shape of the flakes is highly three dimensional and requires a large number of elements in order to accurately model it. That increases the complexity of the model and leads to longer and more intense computational time and power when modeling fluid flow and heat transfer within the unit cell. Additionally, the produced shape does not always produce a space filling tessellation, which is another disadvantage. Figure 2.4 shows two examples of volumetric base unit cell construction.

On the other hand, strut based construction is done by first selecting the location of the nodes in the three dimensional space. The position of the nodes are usually the vertices of a space filling terrestrial. Then the ligament are built on the edges of the space filling terrestrial to achieve the connection between the

nodes. The selection of the space filling terrestrial, the shape of the ligaments and the applied to the ligaments joints are the three factors that determines the properties of the unit cell. The nodes location can be also determined by image processing methods, or statistical methods. Ligaments cross-section can be in any shape; the most common shapes are circles, concaved triangular and convex triangular shapes with convex triangular cross-section ligaments giving the best results [20]. The advantage of this method is that it allows for control on the ligaments shape. It also easier to make sure that the produced unit cell produces a space filling terrestrial. Therefore this method is favored.

2.2.2 Pressure Drop and Volumetric Heat Transfer Coefficient

Since the determination of pressure drop and volumetric heat transfer coefficient characteristics of a foam is easily achieved by experimental methods, the use of unit cell approach in this area was limited. Additionally, fluid flow simulation requires more than one unit cell to achieve fully developed flow. Therefore, geometries constructed of multiples of repeating unit cells were used to obtain pressure drop and volumetric heat transfer coefficient characteristics of foams. Figure 2.6 shows construction of such setup. The results obtained from this method by Wu et.al. [2, 5] complies well with the results obtained by experimental method.

(a) Unit tetrakaidecahedron cell, (b) bulk foams formed by packed tetrakaidecahedrons and (c) computational domain and boundary conditions.

Figure 2.6: Geometry Used by Wu et al [2, 5] to determine Pressure Drop and Volumetric Heat Transfer Coefficient

2.2.3 Thermal Conductivity

Given the complexity of measuring the thermal conductivity experimentally, unit cell approach was widely used in the literature to obtain the thermal conductivity of ceramic foams. Based on the intended application of the foam in a given study; two temperature ranges were studied; high temperature range above $200^{\circ}C$ where radiation plays the major role in the heat diffusion process and a low temperature range where radiation could be neglected [12]

1. Conduction only models.

In 2009, Coquard and Baillis developed a numerical model to estimate the reliability existing models for finding the effective thermal conductivity in the absence of radiation [22] They found that the porosity has the largest

effect in determining the effective thermal conductivity, and the shape of the struts and lumps had a secondary role.

More recent correlations were derived for metal foams by Yang et al [23] and Yao et al [24]. However, these relations were derived for metallic foams and has not been proven to be accurate with ceramic foams.

However, since the intended application of the ceramic foam is in solar receivers, only models considering high temperature ranges with the presence of radiation should be considered.

2. Conduction + Radiation model

A unit cell with BCC structure was used by J.E. Li et.al. to thoroughly evaluate the thermal conductivity of ceramic foams at high temperatures [25]. The effect of both structural and optical properties were studied and validated against available published data. The conductive heat transfer was found analytically by applying model suggested by Boomsma and Poulikakos [23] which only depends on geometrical factors and solid phase thermal conductivity. Radiative heat transfer was also derived analytically making use of the Rosseland approximation and substituting the refractive value of ceramics by n . The equivalent thermal conductivity is then the superposition of both conductive and radiative conductivities.

$$Q_{rad} = -\lambda_{rad} \frac{dT}{dz} \quad (2.4)$$

with

$$\lambda_{rad} = \frac{16n\sigma T^3}{3\beta} \quad (2.5)$$

2.2.4 Radiation Properties

There are three radiation properties that can be determined from a unit cell model; the scattering coefficient, absorption coefficient, and the scattering phase function. For a bcc unit cell with isotropic solid phase reflectance, the radiation properties was found analytically by Li [25]. His derived results were found to be with good conformation with experimental results.

In 1997, X. Fu et al [19] developed a numerical model to measure the transmissivity and the reflectance of a unit cell consisting of a solid cube hollowed by a sphere Fig.2.4 . Reflectance and transmittance values were used to derive the effective radiative properties; the extinction coefficient and the scattering albedo. Simulations for different pore diameter and solid phase reflectance were done. Their findings were within 15% from experimental data.

2.2.5 Exact Modelling Approach

This method utilizes CT scans using x-rays to 3D scan a foam and then foam geometry is reconstructed using computer aided programs. However, this process is not straight forward and require expensive instruments and computer power. Therefore it was not widely used in the literature. In a recent studyby G.L. Vignoles and A. Ortona a model for measuring the effective thermal conductivity

Figure 2.7: Scanned and modeled geometries as obtained from [6].

(conduction + radiation) of a foam using a real geometry and a unit cell shaped geometry was developed [6]. The results verified that simplified geometries used in literature give similar results to exact modeling with less time, cost, and computational power. Simplified geometries results were within $\pm 10\%$ of the exact model values. Another recent paper studied spectral emittance of silicon carbide foams using exact modeling technique [26]. The study also found the size of smallest representative elementary volume to characterize the normal spectral emittance for different porosities and pore diameters. However, up to the knowledge of the author, exact modeling method has been used to model all modes of heat transfer at the same time.

2.3 Concluding Remarks on Literature Review

To summarize and conclude, the unit cell approach is a simplified model that can be used to model fluid flow and heat transfer in ceramic foams using limited time and computational resources. This method was successfully used in the literature and gave accurate results when matched to experimental data. However, the three modes of heat transfer were not modeled simultaneously using the unit cell method. Hence, there is a need to develop a setup utilizing the unit cell simplified approach to model all modes of heat transfer within this type of ceramic foams. This will provide better understanding of the fluid flow and heat transfer phenomena within ceramic foams which is essential to create general guidelines for designing a ceramic foam concentrated solar absorber.

CHAPTER 3

OBJECTIVES AND METHODOLOGY

This chapter presents the general and specific objectives of this work. Also, it describes the methodology used to achieve these objectives.

3.1 Objectives

The objective of this work is to model the three modes of heat transfer (conduction, convection, radiation) simultaneously in a unit cell model of ceramic foams used in concentrated solar absorbers in order to contribute some guidelines for designing the optimum concentrated solar absorber.

3.1.1 Specific Objectives

1. Identify the main parameters affecting the thermal performance of ceramic foam absorbers.
2. Develop a model that considers all modes of heat transfer (conduction, convection, radiation) inside the ceramic foam absorber.
3. Implement a systematic and simplified approach for analyzing the heat transfer inside the ceramic foam absorbers.
4. Suggest some design and operation guidelines for concentrated solar absorbers.

3.2 Methodology

A numerical approach utilizing the unit cell method is selected to tackle the problem. A commercial computational fluid dynamics (CFD) program is to be utilized to solve the fluid flow, energy and radiation equations. Various boundary and operation conditions are studied in order to understand their effect on the overall performance of the ceramic foam as solar absorbers. Some results are compared against published resources for validation.

3.2.1 Detailed Tasks

1. Identify the main parameters affecting the thermal performance of ceramic foam absorbers.

- (a) Conduct an updated literature review to identify all parameters affecting thermal performance of ceramic foam absorbers.
 - (b) Conduct a comparative review to illustrate the importance of each parameter.
 - (c) Select the 4-5 of the most important parameters to be studied.
- 2. Develop a model that considers all modes of heat transfer inside the ceramic foam absorber.
 - (a) Formulate the problem of all modes of heat transfer in ceramic foams.
 - (b) State assumptions and simplifications on the full mathematical model.
 - (c) Develop a numerical model utilizing the simplifications and assumptions.
- 3. Implement a systematic and simplified approach for analyzing fluid flow and heat transfer inside the ceramic foam absorbers.
 - (a) Run - Conduct numerical simulations for proposed scenarios under different design and operating parameters.
 - (b) Analyze the numerical results and extract the main trends.
 - (c) Validate the numerical models against published experimental or numerical data.
- 4. Suggest some design and operation guidelines for concentrated solar absorbers.

CHAPTER 4

PARAMETERS AFFECTING PERFORMANCE OF CERAMIC FOAMS

This chapter is an extension to the literature review with deep and detailed study of parameters affecting the performance of ceramic foams as volumetric solar receivers. It shows - in five tables - the effect of various studied parameters on other variables that effect the performance of foams as solar absorbers directly or indirectly. The calculated sensitivity is defined as the normalized change in the affected parameter over the normalized change in the studied parameter.

$$Sensitivity = \frac{\frac{Affected\ para.\ Max - Affected\ para.\ Min}{Affected\ para.\ Avg}}{\frac{Studied\ para.\ Max - Studied\ para.\ Min}{Studied\ para.\ Avg}} \quad (4.1)$$

Tables 4.1 through 4.5 shows the effects of material properties, porosity, pore

size and other design parameters, characteristics of heated flow, and solar irradiation on various parameters affecting the performance of ceramic foams as solar absorbers.

Table 4.1 shows that the thermal conductivity of the solid foam material and its surface reflectivity are the two major material properties affecting the performance of ceramic foams. The foam's solid material thermal conductivity mainly affects the effective thermal conductivity, temperature distribution in the foam, and the overall efficiency of the foam by small amount. While the surface reflectivity affects the effective radiative properties such as the effective reflectance, transmittance and extinction coefficient. Hence, affecting the radiative conductivity. Therefore, thermal conductivity of the foam solid material and its surface reflectivity are considered as variable parameters in this study.

Tables 4.2 and 4.2 show the great effect of porosity, pore size and other design parameters on the performance parameters of ceramic foams. The effects these design parameters extend to a wide range of performance parameters such as effective radiative properties of foam, fluid flow and heat transfer performance, overall efficiency of the foam, and the air outlet temperature. Therefore, foam porosity and pore size are identified as main design parameters that affect the performance of ceramic foam absorbers. However, since studying these parameter will require a separate geometry and mesh for each case, it was not considered as a variable parameter in this study.

Finally, Tables 4.4 and 4.5 show the effect of operating conditions such as the

fluid type, flowrate, or solar irradiation on various fluid flow, heat transfer and overall performance of ceramic foams. Fluid flowrate of fluid and the Reynold's number are both controlled by changing the mass flux of the fluid. Therefore it is considered as study parameter. The magnitude of the irradiation is the other operation condition considered in this study.

The conclusion made from this chapter can be summarized as follows:

- The performance of ceramic foams is affected by two types of parameters; design parameters and operation parameters.
- The design parameters can be further divided into two types; solid material properties and foam characteristics and treatment.
- The most important solid material properties are the thermal conductivity and the surface reflectivity.
- The most critical foam characteristics and treatment are the porosity and the pore size ie; pore density.
- The most critical operating conditions are the fluid mass flowrate and the magnitude of the solar irradiation.

Hence, the four parameters chosen to be studied in this thesis are: the solid material thermal conductivity and its surface reflectivity, the mass flowrate of fluid and the magnitude of irradiation.

CHAPTER 5

NUMERICAL AND MATHEMATICAL MODELING

This chapter starts by describing the unit cell geometry and construction. The flow field, simulation domain and boundary conditions are then described. Followed by overview on the numerical mesh used. The basic assumptions made to simplify the complex nature of the problem is presented. Finally, the mathematical formulas used in the numerical modeling and its post-processing is shown.

5.1 Geometry

From the literature review section 2.2.1, it has been identified that a truncated octahedron strut consisting of circular beams -ligaments- unit cell gives the closest results to experimental studies in fluid flow and volumetric heat transfer coefficient [2, 5]. Therefore, this method is used to generate the basic unit cell shape. The octahedron edge length is set to $1mm$. The ligaments radius is set to $0.2mm$. This

combinations produces a unit cell with a midsphere radius of $1.5mm$ which is the hydraulic diameter D of the unit cell. The unit cell is placed in the middle of a $2.83mm$ cube to make it more convenient when building multiple unit cell models. Therefore, square faces of the octahedron have only half cylindrical ligaments. The unit cell represents a foam of 89% porosity, and pore density of 12.7 pores per inch PPI. Figure 5.1(a , b) shows the unit cell geometry. The cell The geometrical properties of the unit cell approximately matches the geometrical properties of an available ceramic foam intended for future use in a concentrated solar absorber.

Two multiple unit cells models are constructed using the basic unit cell. Both geometries are two unit cells high and wide. However, the first multiple cells model is two cells long -in the flow and irradiation direction- and the second multiple cells model is three cells long. The multiple unit cells models are abbreviated as 2^3 & $2^2 \times 3$ respectively. In both geometries, a central unit or two unit cells are place in the middle of the assembly then surrounded by half a unit cell from every direction. The multiple unit cells geometries are tilted by 22.5° around the Y and Z directions in order to prevent the front ligaments from shading the ligaments in the back. This was done to improve the optical similarity between the real foam and the models.

The geometrical models are placed in the middle of a flow domain which has same height and width of the models. The length of the domain is the model length plus two unit cells length, with an inlet and an outlet placed $2.83mm$ in front and at the back of the model.

5.2 Mesh

The geometry and the fluid domain is meshed using tetrahedral cells to accurately capture the details of the geometry. A finer mesh is added to the fluid domain near the ligaments in order to capture the boundary layer and the heat transfer. A mesh independency study was done on the single cell model and similar mesh setting was used for all models.

5.3 Assumptions

- **Steady State:** The problem is assumed to be a steady state problem since non of the boundary conditions is changing over time. Therefore, all partial derivatives with respect to time are set to zero $\partial/\partial t = 0$. This is an acceptable approximation since the solar irradiation does not change rapidly through the day, unless a cloud passes and blocks the sun. Also the thermal capacitance of the absorber is not large. Therefore, the system does not take a lot of time to reach steady state if any of the parameters changes.
- **Turbulent Flow:** The flow behavior is assumed to be turbulent since the Reynold's number $Re > 200$ and the widely accepted theory that turbulent flow in porous medium starts from $Re = 100$ [39]. The turbulence model used is the RNG $k - \epsilon$ model.
- **No radiation side scattering:** This assumption is imposed due to the use of symmetry boundary condition on all sides of the unit cell. It can be

visualized as if the radiation beams does not get scattered to the sides. Since we assume that the unit cell is part of a foam, any scattered radiation from the unit cell to the sides is replaced by a similar scattered beam from neighboring cells to the cell of interest. Therefore, the net side scattering will be zero and the assumption is justified.

- **No Temperature jump:** This means that the temperature of the fluid adjacent to the solids have the same temperature.

Air Properties

- **Non Participating:** The air is assumed to be a non participating medium ie; it does not absorb, scatter or emit solar radiation.
- **Variable Density:** Since the temperature change within the domain is greater than $50K$; air density is assumed to follow the ideal gas law.
- **Piece-wise Linear Properties:** Air thermal conductivity, viscosity and thermal capacity are assumed to be piece wise linear with properties values input every $300K$ from $300K$ to $1500K$ at atmospheric pressure.

Solid Material Properties

- **Temperature Independent Properties:** All solid material properties including thermal conductivity, thermal capacity and surface emmisivity are assumed to be constant and does not change with temperature.

- **Diffused Surface:** Emissivity and absorbtivity do not depend on direction.

Therefore emitted intensity is uniform over all directions.

- **Gray Surface:** Emissivity and absorbtivity do not depend on beam wavelength.

5.4 Model Equations & Boundary Conditions

The main equations governing the solution of the problem are the fluid continuity, momentum and energy equations. These equations are obtained from Fluent theory guide and simplified to properly represent the studied problem [9]. The steady state continuity with no source terms is given as:

$$\nabla \cdot (\rho \vec{v}) = 0 \quad (5.1)$$

where ρ is the fluid density and \vec{v} is the velocity vector.

The steady state conservation of momentum without gravitational or external body forces equation is given by:

$$\nabla \cdot (\rho \vec{v} \vec{v}) = -\nabla p + \nabla \cdot (\bar{\bar{\tau}}) \quad (5.2)$$

where p is the static pressure, $\bar{\bar{\tau}}$ is the stress tensor given by:

$$\bar{\bar{\tau}} = \mu \left[(\nabla \vec{v} + \nabla \vec{v}^T) - \frac{2}{3} \nabla \cdot \vec{v} I \right] \quad (5.3)$$

where μ is the molecular viscosity, I is the unit tensor, and the density of the air assuming ideal gas law is given by:

$$\rho = \frac{p_{op} + p}{\frac{R}{M_w}T} \quad (5.4)$$

where p_{op} is operating pressure, R is universal gas constant, and M_w is the molecular weight. The temperature T will be computed from the energy equation which is given by:

$$\nabla \cdot (\vec{v}(\rho E + p)) = \nabla \cdot \left(k \nabla T - \sum_j h_j \vec{J}_j + (\bar{\tau}_{eff} \cdot \vec{v}) \right) + S_h \quad (5.5)$$

Where \vec{J}_j is the diffusion flux of species j , S_h includes the volumetric heat sources, and E described by :

$$E = h - \frac{p}{\rho} + \frac{v^2}{2} \quad (5.6)$$

where sensible enthalpy h is defined as:

$$h = \int_{T_{ref}}^T c_p dT \quad (5.7)$$

The energy equation can be simplified in solid regions to:

$$0 = \nabla \cdot (k \nabla T) + S_h \quad (5.8)$$

The surface to surface radiation model equation can be expressed as:

$$q_{out,k} = \epsilon_k \sigma T_k^4 + \rho_k \sum_{j=1}^N F_{jk} q_{out,j} \quad (5.9)$$

where $q_{out,k}$ is the energy flux leaving the surface k and ϵ_k is the emissivity of the surface. σ is the Stefan-Boltzmann constant. $q_{out,j}$ is the energy flux leaving the surface j . T_k is the temperature of surface k , ρ_k is its reflectivity. F_{kj} is the view factor between surface k and surface j which can be calculated from:

$$F_{kj} = \frac{1}{A_k} \int_{A_k} \int_{A_j} \frac{\theta_k \cos \theta_j}{\pi r^2} \delta_{kj} dA_k dA_j \quad (5.10)$$

Where A_j & A_k are the areas of surfaces j & k respectively. θ_j & θ_k are the angles between the surfaces normal vectors and line r drawn between surfaces centroids. The whole radiation equation is then added to the solid surface energy equation as source terms S_h

5.4.1 Boundary Conditions

For the given problem, boundary conditions are specified at the inlet, outlet, sides, and solid-fluid interface.

Inlet Boundary Conditions

The face of the simulation domain is set as a mass inlet with mass flowrate \dot{m} as a study parameter. The inlet flow temperature T_{in} is set to 300 K. The flow

direction is the positive X direction. Turbulence model is used with the turbulence intensity at the inlet is set to 5% and the turbulent viscosity ratio is set to 10. Thermal boundary conditions are set as

Solar ray tracing model parameters were set as following:

- **Sun Direction Vector:** $X = -1$ $Y = 0$ $Z = 0$
- **Direct Beam Intensity:** is set as a modeling parameter.
- **Diffuse Beam Intensity:** is set to zero.
- **Spectral Fraction:** is set to one.

Therefore, the incoming solar irradiation is inline with the flow direction, and the radiation beams are straight and parallel which is very close to the case of radiation on ceramic foam absorbers when the reflector dish is large and have a large curvature.

Sides Boundary Conditions

All boundary conditions at the sides of the simulation domain are set to symmetry. That forces the normal velocity and all normal gradients of all variables are set to zero at the symmetry planes. Therefore, there will be no convective and no diffusion fluxes through the sides and no heat transfer. Hence, all incoming energy from the inlet will be exiting through the outlet in different forms.

Outlet Boundary Conditions

The outlet is set to a pressure outlet with pressure at the outlet is set to atmospheric pressure. The far field temperature used for radiation calculations is set to be the same as the air exit temperature.

5.5 Performance Parameters Calculation

The results of the numerical simulation is reported in various parameters. Each of which is accordingly defined and calculated. The cell overall performance efficiency η is defined as the ratio of energy transferred to the fluid to the the total incident radiation on the cell.

$$\eta = \frac{\dot{H}_{out} - \dot{H}_{in}}{G * A_{cs}} \quad (5.11)$$

where \dot{H}_{out} & \dot{H}_{in} is the enthalpy flowrate in J/s in and out of the model respectively. G is the solar irradiation in *Watts* and A_{cs} is the cross-sectional area of the unit cell in m^2 .

The total pressure drop cross the unit cell ΔP is calculated by:

$$\Delta P = P_{out} - P_{in} \quad (5.12)$$

However, the pressure drop is reported as $-\Delta P/\Delta x$, where Δx is the geometrical model length.

Volumetric heat transfer coefficient h_v is defined as:

$$h_v = \frac{\dot{H}_{out} - \dot{H}_{in}}{\forall_c (\overline{T_s} - \overline{T_g})} \quad (5.13)$$

h_v is calculated in $W/m^3 \cdot K$ where \forall_c is the volume of the geometrical model in m^3 , $\overline{T_s}$ is the average temperature of the ligaments and $\overline{T_g}$ is the average temperature of air in the model.

The Reynolds number Re is defined based on the superficial velocity at the inlet v_{in} by

$$Re = \frac{\rho v_{in} D}{\mu_{in}} \quad (5.14)$$

where D is the innersphere diameter of the unit cell and μ_{in} is the dynamic viscosity of air at the inlet.

The Nusselt Number Nu is calculated by:

$$Nu = \frac{h_v D^2}{k_g} \quad (5.15)$$

where k_g is the thermal conductivity of air.

A strong relation between the ratio of solar irradiation G in W/m^2 to the mass flux m'' in $kg/m^2 \cdot s$ and many performance parameters are observed. Therefore, this ratio is defined as the specific energy E_{SP} with unit of J/kg

$$E_{SP} = \frac{G}{m''} \quad (5.16)$$

CHAPTER 6

RESULTS

This chapter shows the results and findings of the thesis and presents it in two steps. First, a basic case of a given material properties and operating conditions is studied in detail for a single cell and multiple cells models. Second, a parametric study to understand the effect of different material properties and operating conditions on the performance of foam model is presented.

6.1 Basic Case

In this first section of the results a detailed discussion of the flow field and heat transfer within a single unit cell and assembly of 2^3 and $2^2 \times 3$ unit cells is sequentially presented. The basic case material properties and operation conditions are: $m'' = 12.5 \text{ kg/m}^2 \cdot \text{s}$, $G = 2 \text{ MW/m}^2$, $k_s = 100 \text{ W/m} \cdot \text{K}$, $\epsilon_s = 0.9$.

Table 6.2: Basic Case Conditions

	Parameter	Value	Units
1	Solar Irradiation G	2	MW/m^2
2	Mass Flux m''	12.5	$\text{kg/m}^2 \cdot \text{s}$
3	Specific Energy E_{SP}	160	kJ/kg
4	Superficial Velocity v_{in}	10.2	m/s
5	Reynold's Number Re	2,072	
6	Surface Absorbtivity α_s	0.9	
7	Thermal Conductivity k_s	100	$\text{W/m} \cdot \text{K}$

6.1.1 Radiation Performance

Since the only thermal load on the system is the solar irradiation, it is logical to start the analysis by the studying the performance of the unit cell from a radiation point of view. A key parameter in determining the performance of an absorber is to evaluate how much it reflects, absorbs or transmits an incoming irradiation.

Figure 6.1 shows the absorbed and transmitted radiation as a percentage of the irradiation. The figure shows that 45% of the solar irradiation is transmitted through the single unit cell model. This can be explained by knowing that the

Figure 6.1: Basic case absorbed and transmitted percentage of irradiation.

projection area of the solid ligaments on the inlet area represents 57% of the total frontal area. Therefore, at least 43% of the solar radiation passes the unit cell directly without being interfered by any solids. The extra 2% in the transmitted portion of the radiation is due to the rays that passed the domain by multiple reflections from the ligaments. However, this value is overestimated since the back ligaments are shadowed due to the alignment and orientation of the single cell model. Figure 6.2 clearly shows this shadowing effect. In a more realistic model, the back ligaments are not fully shadowed and some of the radiation will be absorbed them. Therefore increasing the absorbed percentage of irradiation in single cell model and decreasing the transmitted percentage.

The normally reflected percentage of the radiation is only 1 % in all three geometries. This value is smaller than the expected value because the ligament

surfaces are assumed to be diffused reflective surfaces and they reflect the incoming radiation in all directions in the same intensity. Therefore, most of the reflected radiation is reflected to the side and not in the normal direction. In addition, reflected radiation from the back ligaments is partially blocked from escaping the internal geometry by the front ligaments. Therefore, we conclude that the normally reflected radiation is mainly due to the first unit cell, and the contribution of the unit cell at the back can be neglected.

Although the current model does not calculate the scattered radiation on the sides of the computational domain, it is still able to capture the forward and backward scattered portion of the radiation beam which were shown to have the greatest portion of scattering effect [4].

Figure 6.2 shows the solar flux contours on the models. The solar flux values represent the net radiation flux on the surface. Therefore the maximum solar flux observed is equal to $1,800,000 W/m^2$ which is equal to:

$$I_{abs} = \alpha_s \times G \times \cos\phi = 0.9 \times 2,000,000 \times 1 = 1,800,000 W/m^2$$

Also, The font ligament which are at an angle of 45° Degrees with the positive x-axis have maximum solar flux intensity of around $1,300,000 W/m^2$ which is equal to:

$$I_{abs} = \alpha_s \times G \times \cos\phi = 0.9 \times 2,000,000 \times \frac{\sqrt{2}}{2} = 1,272,792 W/m^2$$

Figure 6.2: Solar flux contours on unit cell

6.1.2 Temperature Profiles

The temperature profiles shown in Fig. 6.3 are strongly related to the radiation flux profiles since the absorbed radiation is the only source of energy that heats the ligaments. However, temperature profiles does not follow the absorbed radiation profiles exactly. This is due to conduction within the ligaments which tend to diffuse the heat through the solid. This is the reason why we observe higher temperatures in the tilted ligaments than the normal facing ligaments further in the back which has higher radiation intensity. In this basic case the solid maximum temperature $T_{s,max}$ is 877 K and the minimum temperature $T_{s,min}$ is 723 K while the average solid temperature \bar{T}_s is 801 K .

Figure 6.4 shows the temperature gradients within the solid ligaments in $Kelvin/m$. This quantity is of interest because the it introduces thermal stresses

Figure 6.3: Temperature profiles on unit cell

Figure 6.4: Temperature gradients on unit cell

in the ligaments. During the operation of such materials in concentrated solar absorbers, the material goes under cyclic thermal loads. The increase in the temperature gradients might cause thermal fatigue. A recent study by Ghazi has shown the effect of thermal cyclic loading on the mechanical integrity of the absorber material [1]. Thermal stresses were identified as the main cause of failure of alumina samples. Hence, this point is brought into attention. It is also clearly noticed that the front ligaments are blocking the irradiation from reaching the back ligaments directly.

Figure 6.5: Air temperature contours

Figure 6.5 shows the temperature contours of the fluid field. The average air

temperature at the outlet is 386 K . Two important observations; firstly, the maximum temperature of air happens in the side symmetry plane just behind the first ligament. The reason of such high increase in the temperature is that the velocity of air at the area is very low which limits the transfer of temperature through convection. Secondly, in the same symmetry plane, we observe a large areas of the flow behind the ligaments that have the uniform temperature. This is due to the re-circulation in the flow velocity that enhances mixing and homogenization of temperature.

6.1.3 Velocity Fields

Figure 6.6 shows the velocity magnitude vectors and contours at different cross-sections. Observing the velocity contours and vectors at the centerline we notice the huge increase in velocity while passing through the openings of the unit cell. The maximum velocity is approximately three times the superficial velocity where $V_{in} = 10.6\text{ m/s}$ and the maximum velocity is $V_{max} = 28.8\text{ m/s}$. The effect created is similar to jetting effect. We can notice two recirculating flow areas just below and above the jetting area. Another notice is the increase of average velocity by 30% from 10.6 m/s to 13.8 m/s between the inlet and the outlet zones due to the expansion of air caused by heat addition which decreases its density.

Figure 6.6: Velocity magnitude contours in single cell model

6.1.4 Basic Case Overall Performance

The cell overall performance can be measured by three main parameters; the pressure drop ΔP , the volumetric heat transfer coefficient h_v and the cell efficiency η . Table 6.3 shows dimensional and non-dimensional results for both one cell and 2^3 cells.

Table 6.3: Basic Case Results

	Parameter	Value			% Diff.
		One Cell	2^3 Cells	$2^2 \times 3$ Cells	
1	$-\Delta P/\Delta x$ (kPa/m)	89.1	79.9	72.2	+23.4%
2	$h_v(\frac{W}{m^3 \cdot K})$	8.80×10^5	7.68×10^5	7.44×10^5	+18.3%

6.2 Parametric Study

In order to have a better understanding on the effects of the design and operation parameters on the results, a complete parametric study was done on a unit cell and an assembly of 2^3 multiple unit cells models. A part of the parametric study was done on the $2^2 \times 3$ geometry. The parametric study has all combinations of the following parameters and values.

Table 6.4: Parametric Design

	Parameter	Values	Units
1	k_s	1 - 10 - 100	$W/m^2 \cdot K$
2	α_s	0.1 - 0.5 - 0.9	
3	G	0.5 - 1.0 - 1.5 - 2.0 - 2.5	MW/m^2
4	m''	1.25 - 3.125 - 6.25 - 9.375 - 12.5	$kg/m^2 \cdot s$

A total number of 500 cases are modeled and the summary can be shown in the following sections.

6.2.1 Radiation Performance

Starting the parametric study results analysis similarly. Solar ray tracing method used in modeling radiation allows us to trace the solar irradiation on surfaces and at the inlet and outlet. The solar ray tracing method is independent of fluid flow solution and is only dependent on the geometrical and optical properties of the unit cell. Since we assume that the optical properties such as absorbtivity α_s and reflectivvity ρ_s are independent of temperature, solar ray tracing formulas is solved in the problem initialization step, before solving the full energy equation. Additionally, ratio of absorbed I_{abs} , reflected I_{ref} and transmitted I_{tran} fluxes to the solar irradiation G does not change by changing the irradiation G , mass flux m'' or the thermal conductivity of the solids k_s . It only changes by changing the solids' surface absorbtivity α_s . However, the emitted radiation I_e is not solved by the solar ray tracing method since it requires the solution of the energy equation

(a) One Cell

(b) 2³ Cells

(c) 2² × 3 Cells

Figure 6.7: Effect of solid phase surface absorptivity α_s on absorbed, transmitted and reflected fractions of solar radiation G .

to obtain surface temperatures.

The solution of solar ray tracing equations shown in Fig.6.7 shows the strong relation between the maximum absorbed percentage of incident radiation I_{abs} and the ratio of the projection area of the solids on the inlet area to the inlet area. Since the percentage of projection area of one cell is 65.4 % and for 2^3 cells is 94.1%, the maximum absorbed percentage of solar radiation can be calculated by $\%Area\ projection \times \alpha_s$ which gives us a value of 58.9% for a unit cell and 84.7% for 2^3 cells with both $\alpha_s = 0.9$. However this formula does not apply for lower values of α_s since larger portion of solar radiation is absorbed after a reflection or multiple reflection from the ligaments rather than directly absorbed.

Another noticeable feature of the solar ray tracing results is the unaffected normally reflected portion of solar radiation by the addition of multiple unit cells. This indicates that the normally reflected radiation from the 2^3 cells model is dominated by the first cell in the radiation direction. This can be explained by the nature of the geometry which consists of circular ligaments which reflect the incident radiation diffusely in all directions. Therefore, the addition of one unit cell only introduces circular ligaments that reflects the radiation diffusely and does not effectively contribute to the normally reflected portion of radiation. Hence the main part of the normally reflected radiation is reflected from the flat surfaces which creates the face of the unit cell.

Transmitted part of incident radiation can be divided into two parts;

- **Directly transmitted:** which is the part of radiation rays that goes from the

inlet to the outlet straightly without facing any solids surface in its path.

- **Indirectly transmitted:** which is the part of radiation rays that went from the inlet to the outlet through multiple reflections against the solid surfaces.

The minimum amount of transmitted radiation is the directly transmitted radiation. It can be also calculated from the ratio of projection area of the solids on the inlet area to the inlet area. Where the percentage of directly transmitted radiation is equal to $1 - \text{Projection Area Percentage}$ which gives us a value of 34.6% for a unit cell and 5.9% for 2^3 cells. The directly transmitted radiation is only a function of the geometry and it is not affected by the surface properties of the material. Therefore, we can justify the increase of transmitted fraction of incident radiation - although the total frontal area of the model is the same - by the increase of indirectly transmitted radiation with increasing surface reflectivity ie; decreasing surface absorbtivity α_s .

We notice that the summation of the three components of the radiation equals 100%. This assures the convergence of the radiation intensity since we know that no radiation is scattered from section 6.1.1.

6.2.2 Efficiency

The cell efficiency is defined by Eq.5.11 as the ability of the system to transfer the incoming radiation energy to the fluid. The only sources of losses in the cell are radiation losses. Radiation losses are either direct through inability of the cell to capture the incoming radiation by means of reflection or transmission or

indirect through inability to sustain absorbed radiation by means of radiation emission. However, transmitted radiation and emitted radiation to the backside of the system will be captured by other system components, and therefore will not be direct losses. Therefore, the cell losses reported are the reflected radiation and the emission radiation to the front side. In this subsection, efficiency and radiation losses are presented.

The general trend-line of the efficiency η is decreasing with the increase of specific energy as seen in Fig.6.8. The basic explanation for this trend is the increase in both direct and indirect radiation losses at higher specific energy values. In addition, by increasing the specific energy, the increase of indirect radiation losses is greater than the increase in convection heat transfer to the air. For example, design points 64, 73 and 154 from Table.B by doubling the intensity we notice that the radiation losses increases by 5 folds. However, doubling the mass flux increases the total enthalpy change by only 8%.

We also notice that high absorbtivity surfaces have higher efficiency while the specific energy is lower than $800kJ/kg$ for a single cell or $600kJ/kg$ for 2^3 cells and lower efficiency for higher specific energy levels. In the lower specific energy levels, unit cells with higher absorbtivity surfaces can absorb higher amounts of energy without affecting its radiation losses. A critical specific energy region between $800kJ/kg$ and $1,200kJ/kg$ for a single cell or between $500kJ/kg$ and $700kJ/kg$ for 2^3 cells exists where higher surface absorbtivity becomes a disadvantage due to its higher radiation losses due to higher emissions. The difference in the critical

(a) One Cell

(b) 2^3 Cells

(c) $2^2 \times 3$ Cells

Figure 6.8: Efficiency Vs Specific Energy

(a) One Cell

(b) 2^3 Cells

(c) $2^2 \times 3$ Cells

Figure 6.9: Radiation Losses Vs Specific Energy

specific energy level between one cell and 2^3 cell is due to the difference in the main cause of inefficiency between the two models. While direct radiation losses are the main cause of inefficiency in single cell model, indirect radiation the main cause of inefficiency in 2^3 cells model. However, most solar absorbers used commercially are optically thick, which means they do not allow any radiation to be transmitted directly through their thickness. Therefore, direct losses are reduced and the indirect losses becomes more important. Hence, the results obtained from multiple cells models are considered more realistic and conclusions should be made based on their results.

Although higher absorbtivity materials have less efficiency for specific energies larger than $600kJ/kg$ it can be used efficiently upto specific energy values of $1,000kJ/kg$ where the radiation losses becomes larger than low absorbtivity materials. In designing solar absorbers, the critical specific energy characteristic can be used by placing two foam materials on top of each other; a highly reflective foam in area subjected to specific energy of $2,000kJ/kg$ or more - where radiation losses from highly reflective materials become less- , and a highly absorbing foam elsewhere. Up to the knowledge of the author, this critical value and its usefulness has is new to the literature.

The effect of solid thermal conductivity k_s on the cell efficiency η is less than 3%. Therefore it is not plotted.

Figure 6.10: Air Exit Temperature Vs Specific Energy

6.2.3 Air Outlet Temperature

The main purpose of using ceramic foams in volumetric solar absorber is to heat the passing fluid, mainly air, usually to the highest possible temperature. Therefore the temperature of air after passing the foam is considered the most important parameter in evaluating the performance of a solar absorber. Figure 6.10 shows the strong dependency of air exit temperature $\bar{T}_{g,out}$ on the specific energy E_{SP} . The plot is given at $\alpha_s = 0.5$ and $k_s = 10W/m \cdot K$. However all the other properties combination gives result within $+2\% - 7\%$. Therefore the following formula is proposed to calculate the air exit temperature for $2^2 \times 3$ unit cells model with inlet temperature $T_{in} = 300 K$:

$$\overline{T}_{g,out} = -1.14 \times 10^{-4} E_{SP}^2 + .913E_{SP} + 303 \quad (6.1)$$

Equations such as the proposed equation are very useful in designing solar absorbers for a specific application where a certain temperature fluid exit temperature is desired in terms of specifying the required specific energy to achieve desired temperature.

6.2.4 Pressure Drop

Five extra cases were conducted for each geometry without any thermal load - Solar radiation - to obtain the fluid flow characteristics of the unit cell. Pressure drop was calculated according to Eq.5.12. Results are plotted in Fig.6.11 and a parabolic fit equations are shown. The single cell model has higher pressure drop coefficient due to the entrance effect. Specific permeability, and inertial resistance factor were calculated for a single cell model according to Darcy-Forchheimer Eq.2.1 and found to be $6.68 \times 10^{-8} m^{-1}$ and $968 m^{-2}$ respectively. The results agreed well with previously derived correlation by Wu et al. based on experimental and numerical studies [2]. The 2^3 cells model results are at most 9% less than the derived correlation. The single cell model tends to overestimate the pressure drop $-\Delta P/\Delta x$ by an average value of 32% when compared to the 2^3 cells model.

However, it should be noted that the this pressure drop is only due to viscous forces. In solar absorbers; there will be static pressure loss due to the heat addition to the compressible air that passes through the heated ceramic foam. This pressure

(a) Dimensional form

(b) Non-Dimensional form

Figure 6.11: Pressure drop in dimensional and non-dimensional forms

Figure 6.12: Pressure drop across 2^3 cells with heat addition.

loss contributes significantly to the static pressure loss. However, its calculation is undertaken in the energy and continuity equations. Figure 6.12 shows that pressure drop due to the heat addition may contribute upto 45% of the total static pressure loss. Therefore, the effect of heat addition must be considered while calculating the pressure loss for the solar absorber in order to select an appropriate compressor or a blower that can supply high enough pressure such that the pressure at the exit will not become vacuum pressure.

6.2.5 Volumetric Heat Transfer Coefficient

Figure 6.13 shows the average dimensional and non-dimensional values of volumetric heat transfer coefficient calculated by Eq.5.13, 5.15 for both one cell and

2^3 cells vs the superficial air velocity and Reynolds number. The figure shows that h_v depends mainly on the superficial velocity of the fluid, but is also strongly affected by other parameters as seen in Fig.6.14.

The second main parameter that affects h_v is the difference between the averages of air and ligaments temperatures \bar{T}_s & \bar{T}_g . However, since $\bar{T}_{g,c}$ is mainly affected by the constant air inlet temperature of $300^\circ K$, h_v becomes dependent on \bar{T}_s . The volumetric heat transfer coefficient of one cell is higher 2^3 cells by an average of 20% due to entrance effect.

The results obtained from this section are validated against published numerical studies. Figure 6.14 shows the maximum and minimum Nusselt number vs Reynold's number compared with the correlation obtained by Wu et.al. [5]. The results shows very good agreement between this works results and previously derived correlation. However, the derived correlation was only obtained for a maximum $Re = 800$ and it was extrapolated to extend to our range. Therefore, the difference in the extrapolated range is larger.

CHAPTER 7

CONCLUSIONS

This chapter presents the main conclusions of the thesis including the major findings. The chapter also contains a recommendation section for future research in the field.

7.1 Conclusions

This thesis investigates the fluid flow and the heat transfer in ceramic foams used for high concentration solar receivers. The conducted literature review showed that using a numerical approach with simplified foam geometry gives accurate flow and heat transfer results without expensive computational cost and time. Therefore, a truncated octahedron strut consisting of circular beams -ligaments- was used to generate the basic unit cell shape and to build two different multiple unit cells models.

A basic case simulation with solid ligaments thermal conductivity of $k_s = 100 \text{ W/m} \cdot \text{K}$ and surface absorptivity of $\alpha_s = 0.9$ is subjected to an ir-

radiation of $G = 2 \text{ MW/m}^2$ and a mass flux of air of $m'' = 12.5 \text{ kg/m}^2 \cdot \text{s}$. Radiation intensities, temperature profiles and flow pattern and vectors are thoroughly presented. The average air temperature at the outlet was found to be $T_{g,out} = 386 \text{ K}$ and the cell efficiency was $\eta = 58.9\%$ for a single unit cell model and $T_{g,out} = 447 \text{ K}$ $\eta = 93.1\%$ for $2^2 \times 3$ unit cells model.

A parametric study consisting of 450 design points from different combinations of solids thermal conductivity k_s , surface emmisivity ϵ_s , mass fluxes m'' and solar irradiation G was conducted for models of different number of unit cells. A decline in the models' efficiency is observed with increasing specific energy. A critical value of the specific energy for a single cell model is found to be around 1 MJ/kg where higher solid surface absorbtivity becomes a disadvantage. This critical value occurs at lower specific energy levels, between $0.5 - 0.6 \text{ MJ/kg}$ for multiple unit cells models. Further, pressure drop and volumetric heat transfer coefficient relations with flowrate and Reynolds number were obtained. The relations were found to be with good accuracy with published references.

Based on the work done; the following conclusions are made:

1. The unit cell approach is a simplified method that can be used to study the fluid flow and heat transfer in porous media and can give accurate results when compared to experimental methods.
2. The introduced ratio of radiation intensity flux to mass flow rate flux proved to be the main affecting parameter on the performance of ceramic foams.
3. The volumetric heat transfer coefficient is strongly affected by solid phase

temperature. Therefore, the use of its published values should be limited to the same range of temperatures.

4. The surface reflectivity was found to have much greater effect on the cell efficiency than the thermal conductivity. However, the thermal conductivity plays the major role in the temperature distribution within the cell and the temperature gradients within the ligaments.

7.2 Recommendations for Future Work

Based on the knowledge and experience from this work, this list of recommendations is proposed:

1. The performance of the unit cell should be obtained at many different orientations with respect to the fluid flow and the radiation intensity. A statistical method might be useful in obtaining the average cell property at a random orientation.
2. Similar Unit cell study should be done to study the effect of porosity and pore size on the results.
3. A separate study should be done to determine the size of the multiple unit cell model required to get the actual properties of the foam.
4. A detailed comparison with Local-Thermal-Non-Equilibrium (LTNE) should be done. Multiple correlations can be derived to relate maximum and minimum unit cell values to its average values used in LTNE approach.

5. Since many of the air properties depend on the pressure; the effect of operating the setup at elevated air pressure should be studied.
6. The effect of using a participating gas like carbon dioxide CO_2 or steam H_2O should be evaluated.
7. The effect of reversing the flow direction to be opposite to the radiation flux can be studied.
8. For a better simulation of the actual physical problem, variable intensity profile should be applied to the model. Its effect on the performance should be evaluated.
9. A thermal stress analysis can be carried out based on the temperature gradients in the ligaments to estimate ability of different materials to withstand the operation conditions in concentrated solar receivers without cracking.

Vitae

- Name: Majid Tareq Linjawi
- Nationality: Saudi
- Date of Birth: 25, April, 1991

- Email:

mlinjawi@kfupm.edu.sa

mlinjawi@gmail.com

- Permanent Address:

3504 Abdul Rahman At Tunsu

Ash Shati District

Jeddah 23513-7636

Saudi Arabia

- Bachelor of Science In Mechanical Engineering, 2015 KFUPM
- Master's of Science In Mechanical Engineering - Thermo-fluids, 2018
KFUPM
